Scrub typhus: A prospective, observational study during an outbreak in Rajasthan, India

RAJENDRA PRASAD TAKHAR, MOTI LAL BUNKAR, SAVITA ARYA, NITIN MIRDHA, ARIF MOHD

ABSTRACT

Background. Scrub typhus, a potentially fatal rickettsial infection, is common in India. It usually presents with acute febrile illness along with multi-organ involvement caused by Orientia tsutsugamushi. As there was an outbreak of scrub typhus in the Hadoti region of Rajasthan and there is a paucity of data from this region, we studied this entity to describe the diverse epidemiological, clinico-radiological, laboratory parameters and outcome profile of patients with scrub typhus in a tertiary care hospital.

Methods. In this descriptive study, we included all patients with an acute febrile illness diagnosed as scrub typhus by positive IgM antibodies against O. tsutsugamushi, over a period of 4 months (July to October 2014). All relevant data were recorded and analysed.

Results. A total of 66 (24 males/42 females) patients were enrolled. Fever was the most common presenting symptom (100%), and in 67% its duration was for 7–14 days. Other symptoms were breathlessness (66.7%), haemoptysis (63.6%), oliguria (51.5%) and altered mental status (39.4%). The pathognomonic features such as eschar (12%) and lymphadenopathy (18%) were not so common. The most common radiological observation was consistent with acute respiratory distress syndrome. Complications noted were respiratory (69.7%), renal (51.5%) and hepatic dysfunction (48.5%). The overall mortality rate was 21.2%.

Conclusions. Scrub typhus has emerged as an important cause of febrile illness in the Hadoti region and can present with varying clinical manifestations with or without eschar. A high index of suspicion, early diagnosis and prompt intervention may help in reducing the mortality.

INTRODUCTION

Scrub typhus is a zoonotic infectious disease presenting with acute febrile illness of variable severity. Human beings get infected accidentally when they encroach upon mite-infested rural and suburban areas. It is often acquired during recreational, occupational or agricultural exposure because crop fields are an important reservoir for transmission. It was considered a lethal disease in the pre-antibiotic era and continues to be a public health problem in South Asian and Western Pacific regions.

In India, the first case of scrub typhus was reported in 2009 from Kerala. Though widely prevalent in the Indian subcontinent, specific prevalence data are not available. Apart from this, epidemics of scrub typhus have been reported from north, east and south India. Due to lack of awareness, a low index of suspicion among clinicians, paucity of confirmatory diagnostic facilities and clinical symptoms mimicking other more prevalent diseases such as dengue, malaria and leptospirosis, scrub typhus is under-diagnosed in India, especially in Rajasthan.

The overall mortality varies from 7% to 30%, next only to malaria among infectious diseases.

During an outbreak of acute febrile illness in the Hadoti region in the southern part of Rajasthan, investigations revealed the cause to be due to scrub typhus. Such an outbreak has not been reported earlier from this region. We studied the demographic, clinico-radiological and outcome of patients with scrub typhus during this outbreak.

METHODS

We did this prospective, observational study at a tertiary care hospital in the Hadoti region of Rajasthan during an outbreak of scrub typhus from July to October 2014. All clinically suspected patients with an acute febrile illness (in whom malaria, leptospirosis, dengue fever, viral pharyngitis, enteric fever and urinary tract infection were excluded by history, clinical examination and appropriate laboratory investigations) were included in this study. All demographic data, detailed history, past treatment history/any comorbid illnesses were recorded in a proforma. A complete physical examination, vital signs and relevant investigations were also noted.

All patients were subjected to investigations to establish the cause of fever. These included a peripheral blood smear for malarial parasites, complete blood count, serology for dengue, leptospirosis, scrub typhus, enteric fever and retroviral infections; blood, urine, sputum and/or endotracheal cultures and a smear for acid-fast bacilli using the Ziehl–Neelson’s method. A Mantoux test, X-ray chest, ultrasound abdomen, contrast-enhanced computed tomography (CECT) scan of the thorax and abdomen were ordered as and when required. A CT of the brain and cerebrospinal fluid (CSF) analysis were done, if clinically indicated. Biochemical investigations including fasting blood sugar, renal function and liver function tests were done and recorded.
Scrub typhus serology was tested in batches for IgM antibodies to * Orientia tsutsugamushi* using commercial enzyme-linked immunosorbent assay (ELISA) kits (Panbio Ltd, Brisbane, Australia). The kit uses a specific 56 kDa recombinant antigen of *O. tsutsugamushi* and has a sensitivity and specificity of >90% when compared with recommended gold standard tests, namely the immunofluorescent antibody (IFA) and indirect immunoperoxidase tests. The test was performed as per manufacturer’s instructions. The study protocol was approved by the institutional ethics committee and informed consent was obtained from the patients. A diagnosis of scrub typhus was confirmed when a patient with an AFI had a positive serology for scrub typhus, further strengthened by either the presence of eschar or exclusion of other causes of fever.

Initially, all patients with AFI were treated with empirical antibiotics (intravenous piperacillin–tazobactam and azithromycin) and symptomatic treatment. After confirmation of the diagnosis of scrub typhus, piperacillin–tazobactam was stopped and doxycycline 200 mg per day was started while azithromycin was continued for 7–10 days.

Patients with multi-organ dysfunction (e.g. acute respiratory distress syndrome [ARDS] with or without shock, renal failure, elevated transaminase levels, leucocytosis and thrombocytopenia) were managed with organ support measures as appropriate such as invasive or non-invasive ventilation, inotropic support, renal replacement therapy and blood and blood products.

The presence of organ dysfunction at the time of hospitalization was assessed by using the sequential organ failure assessment (SOFA) score. Organ dysfunction was said to be present if the organ-specific SOFA score was ≥1 and organ failure if the SOFA score was ≥3.7

**Outcome measures**

The primary outcome was in-hospital mortality and the secondary outcomes included length of stay in the intensive care unit (ICU) and hospital, the need for and duration of mechanical ventilation, type of ventilatory support (invasive or non-invasive) and need for dialysis.

**RESULTS**

During the study period, 290 patients were admitted to our hospital with AFI. Of these 66 (22.8%) patients (24 males and 42 females) were diagnosed to have scrub typhus (Table I). Fever was the commonest presenting symptom followed by haemoptysis and cough. The common clinical signs were pedal oedema, jaundice and hepatosplenomegaly. Eschar (8 patients) and lymphadenopathy (12 patients) were seen less commonly.

Low platelet counts and abnormal renal functions were frequently abnormal (Table II). Nearly half our patients (48.5%) had involvement of three or more organ systems. Respiratory dysfunction was the commonest (46; 69.7%), followed by renal (51.5%) and hepatic dysfunction (48.5%). Twenty patients (30.3%) had dysfunction of all five organ systems during the course of hospitalization. Among the 46 patients with respiratory dysfunction, ARDS (34, 73.9%) was the commonest, followed by pleural effusion (30, 65.2%) and pulmonary infiltrates on chest X-ray (12, 26.1%).

Forty-six of the patients required ventilation (Table IV), 18 required dialysis and the overall mortality was 14 (21.2%).

**DISCUSSION**

Scrub typhus is a potentially fatal infection that affects about one
million people every year worldwide. It is a common cause of multi-organ dysfunction and an important cause of admission in ICUs of patients with AFI.

Rickettsial infections have been documented from various parts of India. There have been reports of sporadic outbreaks of scrub typhus mainly in the eastern and southern Indian states with serological evidence of widespread prevalence of spotted fevers and scrub typhus, particularly during the monsoon and post-monsoon months. The outbreak that we studied also occurred during the same period.

During our study, 22.8% (66/290) of patients with AFI presenting to us had scrub typhus, an observation (24.7%) similar to the study from an adjoining region by Sinha et al. age, sex, residential area and occupation are known to influence the occurrence of scrub typhus. People working outdoors tend to be afflicted more often. Most of our patients were 20–50 years of age, an observation similar to Sinha et al. and Madi et al. However, while more women were affected in our series, Rajoor et al. reported more men to be affected. This could probably be because men in the Hadoti region tend to migrate to cities for work and women look after the agricultural work.

The clinical manifestations of this disease vary from minimal disease to severe fatal illness with multi-organ dysfunction. Our patients too presented with similar clinical manifestations and these have been reported in another study from the Indian subcontinent.

We considered the duration of symptoms from the time of onset of fever as this was the first symptom in most patients. Two-thirds of the patients were diagnosed in the second week and had onset of fever as this was the first symptom in most patients. Two-thirds of the patients were diagnosed in the second week and had onset of fever as this was the first symptom in most patients.

TABLE IV. Outcomes of the study patients

Premaratna et al. also postulated that in dark-skinned patients early/very small eschar could be easily overlooked. This difference in incidence of eschar may also be due to variation in serotypes/endemic strain among the regions. One study found that not a single patient presented with eschar. Our findings were similar to those by Razak et al. who concluded that the occurrence of eschar is less frequent among patients from Southeast Asia. Studies have also found a significant difference in the gender distribution of eschars, but the gender distribution was not significantly different in our study.

Eschar is more often than not associated with regional lymphadenopathy. Only 18% of our patients had lymphadenopathy. A wide range (22%–53%) of lymphadenopathy has been reported in different studies, and some have suggested that the presence of generalized lymphadenopathy suggests a late presentation and a worse outcome.

The abnormalities in cell counts, and liver and renal functions in our patients were consistent with those reported in other studies.

Among our patients who presented with any central nervous system manifestations, 26 required CSF examination and only 2 had confirmed meningitis. However, Viswanathan et al. had 17 patients with meningitis among 65 of their patients.

This is possibly because they specifically searched for patients with scrub typhus and meningitis. Scrub typhus should be considered in the differential diagnosis of ‘subacute’ meningitis, especially when accompanied by renal failure or jaundice. Previous studies from India have reported meningoencephalitis in 9.5%–23.3% of patients.

Scrub typhus is a cause of multi-organ dysfunction. Nearly half of our patients (48.5%) had three or more organ systems involved while 20 patients (30%) had evidence of dysfunction of five organs during the course of their hospital stay. Complications in scrub typhus develop after the first week of illness. Narvencar et al. found hepatic dysfunction to be the most common followed by ARDS, circulatory collapse and acute renal failure. We found respiratory dysfunction in over two-thirds of patients, followed by renal dysfunction in over half the patients.

As the main organ dysfunction in our study was respiratory failure, 46 of our patients (69.7%) required mechanical ventilation. Of these, 12 were managed with only non-invasive ventilation, 10 required non-invasive ventilation to be changed to invasive mechanical ventilation and 34 patients were managed at the outset with invasive mechanical ventilation. A study from southern India also showed involvement of the respiratory system in 76.9% of patients and requirement of ventilatory support in 68.9% of patients.

The mortality in patients with scrub typhus has wide variations and depends on the circulatory load of O. tsutsugamushi, early or late presentation and treatment modality. Deaths are attributable to delayed presentation or diagnosis, and drug resistance. Complications such as ARDS, renal failure and hepatic involvement are independent predictors of mortality; most of these were present in our patients.

The case fatality rate for scrub typhus has been 7%–30%, including 10% in Korea to 30% in Taiwan. The mortality rate of 21.2% in our study was slightly higher compared to other studies from India by Mahajan et al. (mortality 14.2%), Kumar et al. (mortality 17.2%) and Rungta et al. while somewhat low as compared to that reported by Lai et al. (mortality 15%–30%) and Griffith et al. Studies have shown inter-strain variability in virulence and since we did not do serotyping and genotyping,
it is possible that the strain type present in our region was a more virulent one causing higher case fatality.

The main strength of our study is that we included confirmed cases of scrub typhus who had IgM antibodies against O. tsutsugamushi. Diagnosis of scrub typhus is difficult in India because of its varied clinical presentation, absence of eschar in many patients, and lack of availability of specific tests (ELISA/serological tests). In developing countries with limited resources such as India, we suspect that the diagnosis of scrub typhus should be based largely on a high index of suspicion and careful clinical, laboratory and epidemiological evaluation. It is prudent to recommend empirical antibiotic therapy in patients with acute febrile illness with evidence of multi-organ involvement.

Conclusion

Scrub typhus is prevalent in many states of southern and eastern India, but outbreaks have been occurring in other parts too, including in Rajasthan. Mortality in these patients is most often due to multi-organ dysfunction.

ACKNOWLEDGEMENTS

We would like to thank all the healthcare staff involved in the care of our patients.
